1. The material is not to be used for the purpose of the investigation.

10 June 1948/Copied/pr

being received from radioactivity as much as it would have been from the accepted tolerance of external radiation, 0.1 r/24 hr. Other than fish, no food product was found which contained more than twice the normal radioactivity of human flesh. No detectible amount of Pu was found in any food product. The conclusion of the writer, from the above figures and others known to him, is that the hazard from radioactivity to an adult living continuously on Bikini Atoll indefinitely, subsisting entirely on local food products, would be less than the hazard of a single journey by air from there to the United States. When it is remembered that the two dangerous long-lived fission products, Sr and Cs, are not now present at Bikini, that the fission-product activity still present will have decayed to about 20% of its present value after one more year, and that of food eaten somewhere between 1% and 10% normally is retained by the body, it becomes obvious that after a few more years these islands will not constitute a radioactive hazard to anyone. As will be shown in more detail in the accompanying reports and below, substantially the same close localization of the radioactivity and relative absence of significant areas from the radioactive effects of atomic bomb explosions may be expected on the land and in the waters of the United States.

The foregoing paragraphs constitute a brief summary of those conclusions of military significance which have accrued from the BIKINI SCIENTIFIC RESURVEY. The accompanying reports give the detailed data in the words of the different scientists who obtained it. Some of these are discussed in detail below.

As CHILTON (APA-38) crossed the sill of Enyu Channel we were disappointed to observe that the water, instead of being marvelously clear, as it had been when the first units of Task Force One entered the lagoon, was as opaque as that off Point Loma, and the writer, at least, concluded that something sinister had indeed occurred. It was found difficult to explain this change, however, on grounds connected with radioactivity. It was known that immediately after Test B there was a large increase in the bacterial population, probably due to nutrients from animals killed by the explosion, and that this might later have been reflected in an increase in the plankton content of the water; but when it was calculated that even the large contribution of Task Force One to the nitrogen and phosphorous content of the water amounted to less than 1% of what was there to start with this idea was abandoned. Late in the summer it was discovered that bacterial levels had resumed their pre-explosion status, and the ghost of bacterial increase was laid to rest. Then some of us remembered that even before Test A the water had

become definitely and progressively more opaque. At the time, this had been thought due to contamination by the Task Force, but when the above-mentioned calculation showed the fallacy of this reasoning, we began to wonder whether the effect might not be seasonal, and associated with the dropping off of the Trades. Four leading natives from the former population of Bikini were brought back, told to observe and record everything that had changed, and taken on a tour of all the islands. They recorded in wearysome detail all the new construction, and found some papaya plants which may have grown from seeds left by Task Force One, but said nothing about the water, even after they had been chivvied in and out of the surf and over reefs until they asked for mercy. They were then asked leading and finally direct questions about the water, but would not concede that it was different from what it always had been. This seemed to establish the effect as seasonal, but recourse was had to other controls.

The water at the southern end of Eniwale Lagoon, away from the harbor area, was clearer than that of the windward end of Bikini, but not remarkably so. The water at the windward end of Rongerik Atoll was definitely much clearer than that of the corresponding position at Bikini, but even at Rongerik, when a sea was formed in the lagoon by a strong southerly wind and surf beat upon the beaches, the water rapidly became opaque and there was some silting. The conclusion is that the relatively greater opacity of the water at Bikini during the period of the resurvey was due to the heavy swell which enters through Enyu Channel at this time of year, but which is almost completely absent in the winter season when the Trades are steady. The other atolls do not have a large opening to the south and are much less disturbed by the summer swells. Although the origin of the turbidity seems well disposed of by the above observations, it would be desirable to have monthly determinations of water transparency made at the same location in the target area over a period of a year.

On the basis of the chemists' work some detail can now be added to the phenomena of the Baker explosion. Within a tenth of a second after the explosion some 275-day Cerium 144, which is one of the more abundant and troublesome long-lived isotopes, had been formed as the end product of a fast radioactive chain beginning with Xenon 144. Under the great heat and pressure still prevailing, this was mineralized in a way not possible in a reasonable amount of time in the laboratory, to an extremely insoluble and hitherto unknown form, which in all probability can never be absorbed by plants or animals. Within a few minutes a large fraction of all the fission products which ultimately remained in the area were in the water of the lagoon; an exception being 53-day Strontium 89, another long-lived substance, some of which was

will be the form of immediate fallout, and will depend on the
inner edge of the area of precipitation. The result was that
only about half the amount of Strontium 90 finally produced
was deposited on target ships. Within a few minutes all the
radioactive products which remained in the lagoon were in
the water, which was turbid with debris from the bottom and
very finely powdered. Photographs taken shortly after the
cloud cleared away show an asymmetrical patch of milky
water about the size of the target array. All the fissionable
material from the explosion and the following long-lived
fission products, Thorium, Plutonium, Uranium, Iodine,
Cesium, Barium, Strontium, and others, as well as many
short-lived fission products, were quickly and permanently
adsorbed on the suspended material and carried to the bottom,
where all but an insignificant fraction still are. Thirty-
three year Cesium was not so adsorbed because of the large
quantity of the chemically similar element Sodium already
present. Twenty-five year and longer lived radio-Strontium
was not adsorbed because the relatively large amount of
chemically identical neutral Strontium normally present in
sea water had saturated the surface of the adsorbent. Only
a small fraction of the various radioactive Barium
isotopes was carried down because of the tendency of this
element to form complex anions with chloride, sulfate, and
nitrate. More than 90% of these anions, however, had been
carried off to sea by the current. The only significant
contribution to the activity of the bottom was made by the
adsorption of Strontium 90, which otherwise would have been a more significant
contributor to the present activity of the bottom.

The radioactive materials carried down by the process
just described are by no means evenly or symmetrically
distributed on the bottom; the details of the distribution
are so complex that only a rough, qualitative estimate of
the total radioactive material on the bottom has been possible.
The greater part of the material was deposited near the
center of the target array, but patches of as much as forty-
fold higher activity per unit weight are found farther out,
and the data suggested that the most active materials were
deposited near the outer edge of the column. In most cases,
the most active deposits are at the surface of the bottom,
but in some places rich deposits are overlain by other ones.

At the present time there are no burrowing
animals in the bottom, and having the highly radioactive debris
just at its surface right through the top of the column
is not a good thing. Bacteria are present in the water
near the surface of the bottom, but they are not available
to plants, which grow on the altered material. These plants
are eaten by small fish, which select almost all the radio-
active material through the gut. Small fish with the small

fraction of radioactive material they have retained in their tissues are in some cases by large fish which were present when the radioactivity entered the lake. In the case of the fish which were present in the lake and were of the same species as the fish which were present in the lake at the time of the accident, the fish which were present in the lake at the time of the accident are the only ones which have retained a certain amount of it at the present time.

It is time to consider the ultimate fate of the radioactive material now in or on the lake bottom. Fishes promote absorption by food is much faster than by biological processes. Within a year lake fish will have reduced the activity in total energy to 50% of what it is now, and the flesh of the lake fish will not, on the average, be as radioactive as normal ocean fish. In five years, only 25% of the present activity will remain, and radioactivity of fish will be completely lost in the lake bottom. In 10 years less than 1% of the present radioactivity will remain. The radioactive material absorbed by biological processes without promptly being excreted or excreted will be lost in the lake bottom. The radioactive material absorbed by biological processes without promptly being excreted or excreted will be lost in the lake bottom. The radioactive material absorbed by biological processes without promptly being excreted or excreted will be lost in the lake bottom.

The idea that plants and animals may concentrate radioactive material has often been discussed. By way of definition, radioactive material may be termed concentrated when the amount of radioactive energy per unit of weight or volume of product exceeds the corresponding amount per unit weight or volume of the material from which it was derived. For food received in the case of an animal, concentration of radioactive material by plants had definitely occurred five days after the test of the lake. The factor of concentration was approximately one hundred fold, and several out of 100 samples showed concentration over 100 fold. The average concentration was about 10 but many cases of concentrations less than unity were observed. At that time, the concentrations of radioactivity in the water and in the water were approximately equal, so that the question of what is to be done with the radioactivity of the lake is not wise. The fish collected at that time exhibited no gross concentration, though the gills, liver, and spleen of some of the fish did show concentration as high as a factor of ten. The plants collected in the lake a year later, after several washings with salt water to remove the gills, were invariably much less radioactive than the food from which they grew though one sample did show a definite trace of radioactivity associated with its cellulose content. One fish (a cyprinid) caught near the edge of the target array a year later showed a gross concentration factor of 1.5.

over the material found in its gut; most of the activity was in its liver. No other fish showed gross concentration, although about a third showed a greater concentration in the liver than in the gut.

The marked concentration of radioactivity by plants five days after Test B, and the reverse effect a year later, undoubtedly are reflections of the different identities of preponderant radiators at the two times. Radioiodine, Rubidium, Ruthenium, Iodine, 13-day Cesium (55-year Cesium, though present at that time, was an insignificant contributor), Strontium, and Barium, none of which were present in appreciable amounts a year later, would not have been carried to the bottom by the sediment. Overstreet and Jacobson (OH 3588) have shown that of the radionuclides Strontium, Yttrium, Cerium, Zirconium, and Columbium, only the first was appreciably concentrated by dwarf pea plants.

It will be seen from the above considerations, that although specific cases of concentration of radioactivity by plants and animals do occur, the gross effect of biological processes is overwhelmingly in the direction of dilution. Though it is possible that after an atomic event a particular warehouse might be made more radioactive than the surrounding country, the main effect of plants and animals would be to hasten the time when contaminated areas could be returned to normal use.

One of the most feared effects of radioactivity is the possibility of producing monsters by genetic changes. At Bikini more than a thousand species of organisms have been exposed to unprecedented amounts of radioactivity, and many of them have reproduced through several generations since. A most careful search of the area by competent biologists, ichthyologists, botanists, and an entomologist, in the course of which tens of thousands of specimens were examined, failed to reveal a single aberrant form. It would seem that this danger is illusory.

The Experimental Biology Group, particularly, was on the lookout for effects of radiation on those physiological processes where it was considered most likely to show -- reproduction, metabolism, and enzyme activity. The only effect found was an increase in catalase activity in certain algae. This was believed beneficial to the organisms in question.

In using the results of the Bikini resurvey, with other information, in planning the defense of the United States, two points need special consideration. At Bikini three abundant long-lived fission products -- Strontium, Cesium, and Ruthenium -- were not carried down by the mud because sea water contains abundant material in solution to hold them

back. In fresh water and on the land this will not be the case, and the area of heavy contamination will be even more sharply limited and defined than at Bikini. The second point is that in heavily contaminated fresh water or land areas 25-year Strontium and 33-year Cesium, not now present at Bikini, will maintain significant external radiation levels long after the long-lived fission products now present at Bikini have decayed into the cosmic-ray background.

Outside the areas of heavy contamination in land or fresh-water masses there will be a gradual spread of traces of wind, animal, and crop-borne radioactivity, and these probably will be detectable over a wide area for some time, as they now are at Bikini. Realistically considered, these traces will offer no hazard at all comparable to the danger of driving an automobile, crossing the street, or living in a house with live electric wiring. Even those who might have qualms about eating fish and coconuts from Bikini Atoll have the comfort knowing that there are valuable crops for every kind of soil which could be profitably harvested and used, even though they reeked of Plutonium. Whiskey from contaminated corn would be just as harmless as that from the undeveloped mountains of Kentucky. Contaminated wheat, barley, potatoes, and rice also could be used in the fermentation industries which now take appreciable fractions of the output. Sugar from contaminated cane or beets could be served on the table without any reservations. The loss to agriculture will be confined to heavily contaminated areas -- probably less than five square miles per bomb.

One of the avowed objects of the resurvey was to conduct researches of purely scientific interest, particularly those begun by Task Force One. Over three quarters of the man-hours of the mission, and well over that proportion of the funds, were so used. Although nothing particularly new or startling was discovered, considerable data was added to the fund of knowledge concerning the geology, oceanography, and biology of these islands. A good picture of the work may be had from the accompanying reports, but final appraisal must await publication in the standard scientific journals. It is considered possible and desirable to continue this work at a lower rate and higher efficiency. A suggestion as to how this might be done is given at the end of this Section.
